(Received 19 October 2018; published 4 January 2019)

A novel form of amorphous matter characterized by marginal stability was recently discovered in the mean-field theory of structural glasses. Using this approach, we provide complete phase diagrams delimiting the location of the marginally stable glass phase for a large variety of pair interactions and physical conditions, extensively exploring physical regimes relevant to granular matter, foams, emulsions, hard and soft colloids, and molecular glasses. We find that all types of glasses may become marginally stable, but the extent of the marginally stable phase highly depends on the preparation protocol. Our results suggest that marginal phases should be observable for colloidal and non-Brownian particles near jamming and for poorly annealed glasses. For well-annealed glasses, two distinct marginal phases are predicted. Our study unifies previous results on marginal stability in mean-field models and will be useful to guide numerical simulations and experiments aimed at detecting marginal stability in finite-dimensional amorphous materials.

I. INTRODUCTION

Twenty years ago, a unified phase diagram for amorphous matter [1] motivated the search for similarities and differences between the properties of a broad range of materials, from granular materials to molecular glasses [2]. It is now well established that in the presence of thermal fluctuations, dense assemblies of atoms, molecules, polymers, and colloidal particles undergo a glass transition [3,4] as the temperature is decreased or the density increased. In the absence of thermal fluctuations, solidity instead emerges by compressing particles across the jamming transition [5,6], relevant for foams, non-Brownian emulsions, and granular materials. These two transitions have qualitatively distinct features.

Models of soft repulsive spheres faithfully capture this diversity [7,8], as shown in Fig. 1. The relevant adimensional control parameters are the packing fraction $\varphi$ and the ratio of thermal agitation $k_B T$ to the interaction strength between particles $\epsilon$. A dense assembly of soft particles transforms into a glass when thermal fluctuations decrease. Glasses can also be obtained by compression at constant temperature, and in particular the limit $\epsilon \to \infty$ at constant $T$ corresponds to compression of colloidal hard spheres. At high density and temperature, the particles constantly overlap and the system behaves identically to glass-forming liquids. Intermediate densities and temperatures describe the glass transition of soft colloids. Jamming transitions are observed in the athermal regime $k_B T/\epsilon \to 0$ relevant for granular materials, foams, and non-Brownian emulsions. Because this occurs deep inside the glassy phase at $T = 0$, jamming transitions are protocol dependent and occur over a continuous range of packing fractions $\varphi_J$ [9–12].

The phase diagram in Fig. 1 organizes the physics of a broad variety of materials by describing how fluids lose their ability to flow, but incorrectly suggests that the solid phase has similar properties across a broad range of physical conditions. In fact, while ordinary glasses formed by cooling dense liquids behave roughly as crystalline solids with a high density of defects [13,14], glasses formed by compressing granular materials or non-Brownian emulsions across their jamming transition display unique properties distinct from ordinary solids [5,6]. For example, they may respond to weak stresses with very large deformations and their low-frequency excitations are very different from phonons [15–17]. These properties were theoretically explained by invoking marginal stability [18,19]: Because these glasses are formed by zero-temperature compression across a rigidity transition, they have barely enough contacts to be mechanically stable. From this observation, several anomalous properties of athermal glasses in the vicinity of jamming can be understood [20].

Theoretical calculations in the framework of the mean-field theory of the glass transition [11,21–24] have confirmed these ideas and suggested in addition the existence of two distinct types of amorphous solids separated by a sharp phase transition [25,26]. One phase is the normal glass, which corresponds to a free-energy basin that responds essentially elastically to perturbations, as any regular solid. The second is a Gardner glass [27,28]. The Gardner glass is marginally stable due to full replica symmetry breaking, as in mean-field spin glasses [29]. Physically, marginal stability implies the existence of long-range correlations in the vibrational dynamics [30,31], an excess of low-frequency modes [32,33], unusual rheological properties [34–36], and system-spanning responses to weak, localized perturbations, manifested, for instance, by diverging mechanical susceptibilities [34,37,38]. The Gardner phase may thus provide an elegant route to understand the nature of a multitude of experimental observations of glassy excitations [25,26]. Explicit mean-field calculations for the location of marginally stable glasses were carried out for hard [25,26] and soft [34,39,40] potentials,
Materials may have distinct properties, depending on both physical conditions, covering all regimes illustrated in Fig. 1. For a glass prepared at any given location in this recent flurry of results suggests that distinct glassy marginal stability of glasses prepared in a wide range of soft repulsive spheres in the limit of infinite spatial dimensions, suggesting that glasses obtained by a fast quench. The extent of the marginally stable glassy phases. This is the central goal of the present work.

which justifies our effort to study it as well. While the expression of the harmonic potential is the same regardless of spatial dimension, we have extended the standard definitions of the WCA and IPL models in $d = 3$ to arbitrary dimension $d$. This is done because thermodynamic stability and the existence of the thermodynamic limit, a prerequisite for performing the theoretical development described below, require the potential to decay faster than $r^{-d}$ in dimension $d$ [51].

We consider the thermodynamic limit for $N$ particles in a volume $V$, both going to infinity at fixed number density $\rho = N/V$. When $d = \infty$, we can consider monodisperse particles, as crystallization or mean-field effects are no longer the worrying issue it is in finite dimensions [52,53]. Our adimensional control parameters are the packing fraction $\psi = NV_0(\sigma/2)^d/V$, defined as the fraction of volume covered by particles of diameter $\sigma$ ($V_0$ is the volume of a $d$-dimensional unit sphere), and the scaled temperature $T/\epsilon$ (in the following, we will set $k_B = 1$). To obtain a nontrivial phase diagram in the limit $d \to \infty$, the packing fraction has to be rescaled as $\hat{\psi} = 2^d \psi/d$. Note that in that in the case of the IPL model, the form of the interaction potential leads to a unique control parameter $\Gamma = \hat{\psi}/T^{1/4}$. We also define rescaled gaps between particles $h = d(r/\sigma - 1)$ and rescaled potentials $\tilde{v}(h)$ such that $\lim_{d \to \infty} v(r) = \tilde{v}(h)$:

$$\tilde{v}_{\text{ham}}(h) = \frac{1}{2} h^2 \theta(-h), \quad \tilde{v}_{\text{qm}}(h) = e^{-4h}. \quad (4)$$

We will be particularly interested in mean-square displacement (MSD) between configurations. In finite dimensions, they are usually defined as $D(X, Y) = \frac{1}{N} \sum_i |x_i - y_i|^2$, where $X$ and $Y$ represent two configurations. Finite values for the MSD in infinite dimensions are obtained by defining $\Delta(X, Y) = d^2 D(X, Y)/\sigma^2$.

In the following section we summarize the formalism that allows us to compute the thermodynamic properties and the phase diagram for the above models.

### III. THEORETICAL METHODS

The general strategy of our work is to mimic the following experimental protocol. During the gradual cooling or compression of a glass-forming liquid, the equilibrium relaxation time $\tau_E$ of the system increases very sharply. For a given protocol, there comes a moment where the system falls out of equilibrium; this represents the experimental glass transition, at state point $(T_g, \hat{\psi}_g)$. After this moment, the system follows a "restricted" equilibrium, where the amorphous structure frozen at the glass transition is adiabatically followed at different temperature and density, $(T, \hat{\psi})$. Our analytical strategy follows this protocol closely. We draw an analytical strategy follows this protocol closely. We draw an

$$\frac{Z(T, \hat{\psi}|Y, \Delta_r)}{Z(T_g, \hat{\psi}_g)} = \frac{T}{N} \int \frac{dY}{Z[T_g, \hat{\psi}_g]} e^{-\beta Y V[Y]} \times \ln Z[T, \hat{\psi}|Y, \Delta_r], \quad (6)$$

where $Z[T_g, \hat{\psi}_g]$ is the standard configurational integral at $(T_g, \hat{\psi}_g)$. The free energy has to be computed for the parameter $\Delta_r$ verifying $\partial_{\Delta_r} f_g = 0$ [57]. Note that the density dependence of the free energy is encoded by the interaction length scale $\sigma$ of the potential, which can be changed to induce a change in packing fraction.

Performing the disorder average in Eq. (6) is challenging. Translational invariance, necessary to use saddle-point and perturbative methods, is broken by the presence of disorder. To compute the glass free energy in Eq. (6) we use the replica method and introduce $s + 1$ identical replicas of the original atomic system to undertake the computation [26,54,57]. The master replica represents the initial glass at $(T_g, \hat{\psi}_g)$, while the $s$ other slave replicas represent the glass at $(T, \hat{\psi})$. The glass free energy can then be expressed in terms of the MSD between the different replicas. The MSD between any slave replica and the master replica are parametrized by $\Delta_r$. We make the simplest assumption, called replica symmetric, and consider that all slave replicas are equivalent [57] at a distance $\Delta$ from each other. At the end of the computation, we take the analytic continuation $s \to 0$ and obtain the replica symmetric glass free energy

$$\frac{2}{d} \beta f_g = \frac{2\Delta_r}{\Delta} + \ln(\pi \Delta/d^2) + \hat{\psi}_g \int_{-\infty}^{\infty} dh \, P(h) f(h), \quad (7)$$

defining for simplicity $\eta = \ln(\hat{\psi}/\hat{\psi}_g)$:

$$q(\Delta, \beta; h) = \int_{-\infty}^{\infty} dy \, e^{-\beta \psi(y)} e^{-(h - \Delta y^2)/2\Delta} \sqrt{\pi \Delta}, \quad (8)$$

and

$$P(h) = e^{\eta} q(2\Delta_r - \Delta, \beta; h),$$

$$f(h) = \ln q(\Delta, \beta; h - \eta). \quad (9)$$
Compressing and decompressing a glass corresponds to \( \eta > 0 \) and \( \eta < 0 \), respectively. The glass free energy should be computed with the thermodynamic values for \( \Delta \) and \( \Delta_r \), determined by setting to zero the derivatives of \( f_g \) with respect to these parameters, which provides two implicit equations for \( \Delta \) and \( \Delta_r \):

\[
2\Delta_r = \Delta + \hat{\phi}_g \Delta^2 \int_{-\infty}^{\infty} dh \frac{\partial}{\partial \Delta} [P(h) f(h)], \\
2 \frac{\Delta}{\Delta_r} = -\frac{\hat{\phi}_g}{\Delta_r} \int_{-\infty}^{\infty} dh f(h) \frac{\partial}{\partial \Delta_r} P(h).
\] (10)

### B. Dynamic glass transition

Our method focuses on glasses prepared at \((T_g, \hat{\phi}_g)\), below the dynamical transition. Our first task is thus to compute the dynamical transition line \( T_d = T_d(\hat{\phi}_g) \) for the models presented in Sec. II. To do so, let us consider the special case \((T_g, \hat{\phi}_g) = (T, \hat{\phi})\) in the above construction. In that case, \( \Delta = \Delta_r = \Delta_g \) is a solution of \( f_g \) in Eq. (10) if the glass MSD \( \Delta_g \) verifies

\[
\frac{1}{\hat{\phi}} = -\Delta_g \int_{-\infty}^{\infty} dh e^h \ln \left( \Delta_g, \beta; h \right) \frac{\partial q(\Delta_g, \beta; h)}{\partial \Delta_g} = \mathcal{F}_D(\Delta_g).
\] (11)

For the models considered here, the function \( \mathcal{F}_D(\Delta) \) is positive, vanishes for both \( \Delta \rightarrow 0 \) and \( \Delta \rightarrow \infty \), and has an absolute maximum in between. This means that Eq. (11) has a solution at temperature \( 1/\beta \) only if \( 1/\hat{\phi} \) is smaller than or equal to the maximum of \( \mathcal{F}_D \) with respect to \( \Delta \). Glassy states at \( T \) thus exist only at packing fractions higher than \( \hat{\phi}_d \), defined by

\[
1/\hat{\phi}_d = \max_{\Delta} \mathcal{F}_D(\Delta). \tag{12}
\]

We numerically solve Eq. (12) for all temperatures and find the dynamical transition line \( \hat{\phi}_d(T) \), or equivalently \( T_d(\hat{\phi}_g) \). The result is represented for the harmonic potential in Fig. 2. The line separates liquids that flow from dynamically arrested ones. The qualitative behavior of \( T_d(\hat{\phi}_g) \) in the WCA model is similar to that of harmonic spheres presented in Fig. 2. In both cases, the dynamical transition temperature is an increasing function of \( \hat{\phi} \) and is defined for \( \hat{\phi} > 4.8067 \), which corresponds to the dynamical transition for hard spheres [11]. In the high-density limit, the WCA model behaves as the inverse power law potential and the dynamical transition scales as \( T_d \sim \hat{\phi}^{4.3} \). The coefficient of proportionality is \( 1/\Gamma_d^4 \), where \( \Gamma_d = 4.304 \) is given by the dynamical transition of IPL glasses.

### C. Adiabatically following the glass properties

We focus on glasses prepared at \((T_g, \hat{\phi}_g)\) in the dynamically arrested phase. We study their thermodynamic properties when adiabatically brought to temperature and packing fraction \((T, \hat{\phi})\). In particular, we compute the average potential energy per particle \( \hat{\epsilon}_g \), given by the derivative of \( f_g \) in Eq. (7) with respect to the inverse temperature

\[
\hat{\epsilon}_g = \frac{1}{d} \frac{\partial (\beta f_g)}{\partial \beta} = -\hat{\phi}_g \frac{1}{2} \int_{-\infty}^{\infty} dh P(h) \frac{\partial}{\partial \beta} f(h). \tag{13}
\]

FIG. 2. Equilibrium mean-field phase diagram for harmonic spheres. The dynamical transition \( T_d \) (red line) separates liquids that flow (above) from dynamically arrested ones (below). We select equilibrium glasses in the dynamically arrested region, for example, \( g_1, \ldots, g_4 \), and follow each glass adiabatically in temperature and packing fraction. The corresponding state-following phase diagrams are presented Figs. 3(a)–3(d). Glasses equilibrated above the line \( T_d \) (dashed line) are jammed once minimized to \( T = 0 \), while glasses selected below the line are unjammed at \( T = 0 \). The state-following phase diagrams of glasses prepared at \( \hat{\phi}_g = 13 \) (vertical dashed line) are presented in Figs. 3 and 4.

The energy is to be computed using the thermodynamic values for \( \Delta \) and \( \Delta_r \), which solve Eqs. (10).

We employ the following strategy to numerically solve the equations, find the values of \( \Delta \) and \( \Delta_r \), at each state point, and consequently compute the glass potential energy. First, we compute the MSD \( \Delta_g \) of the glass at \((T_g, \hat{\phi}_g)\) by numerically solving Eq. (11). Starting at \((T_g, \hat{\phi}_g)\) with the initial condition \( \Delta = \Delta_r = \Delta_g \), we gradually change the temperature and/or packing fraction by small steps towards \((T, \hat{\phi})\). At the beginning of each step, we use the values \( \Delta \) and \( \Delta_r \) of the previous step as initial guesses. We then solve iteratively Eqs. (10) by computing the right-hand side of the equations to obtain new estimates of \( \Delta \) and \( \Delta_r \) until convergence is reached. We repeat this procedure until the final state \((T, \hat{\phi})\) is reached.

### D. Gardner transition

The glass free energy \( f_g \) defined in Eq. (7) is derived assuming that the symmetry under permutations of replicas remains unbroken. At each state point, we must check the validity of this assumption. In practice, we check that the replica symmetric solution is a stable local minimum of the free energy. The replica symmetric solution becomes locally unstable against replica symmetry breaking when one of the eigenvalues of the stability operator of the free energy changes sign [29]. This so-called replicon eigenvalue can be expressed in terms of \( \Delta \) and \( \Delta_r \) as [60]

\[
\lambda_R = 1 - \frac{\hat{\phi}_g}{2} \Delta^2 \int_{-\infty}^{\infty} dh P(h) f''(h). \tag{14}
\]

At each state point, the converged values for \( \Delta \) and \( \Delta_r \) are used to compute the replicon eigenvalue. In the replica symmetric, or simple glass phase, the replicon is positive. The replicon might become negative upon cooling or compressing
a glass, signaling its transformation to a replica symmetry-
broken glass. We show that in most cases, the simple glass
transforms into a marginally stable glass, characterized by
full replica symmetry breaking (FRSB). This is a Gardner
transition, in analogy to a similar phase transition found at
low temperature in some spin glasses [27,28].

In the marginally stable phase a complex, full replica
symmetry-breaking solution should be used to derive accu-
rately the thermodynamics of the glass [60]. Such a solution
is parametrized by a function $\Delta(x)$, for $x \in [0, 1]$, associ-
ated with the distribution of mean-square distances between
states. While computing the full function $\Delta(x)$ requires a
rather heavy numerical procedure [61], one can estimate its
states. While computing the full function $\Delta(x)$ requires a
rather heavy numerical procedure [61], one can estimate its
shape close to the transition where $\lambda_R = 0$, by a perturbative
calculation [61,62]. One gets

$$
\Delta(x) \sim \begin{cases} 
\Delta(\lambda) - \epsilon \Delta(\lambda), & x < \lambda - \epsilon \\
\Delta(\lambda) + \Delta(\lambda)(x - \lambda), & \lambda - \epsilon < x < \lambda + \epsilon \\
\Delta(\lambda) + \epsilon \Delta(\lambda), & x > \lambda + \epsilon.
\end{cases}
$$

Here $\lambda$ is called the breaking point or mode-coupling-theory
parameter. It is related to the mean-field dynamical critical
exponents of the transition [25,63–65] and, presumably, to the
universality class of the transition beyond mean-field theory
[66]. At the transition point, $\epsilon \to 0$ and the constant replica
symmetric solution $\Delta(x) = \Delta(\lambda) = \Delta$ is recovered. Because
$\Delta(x)$ must be monotonically decreasing for $x \in [0, 1]$, a
consistent FRSB solution requires $\lambda \in (0, 1]$ and $\Delta(\lambda) < 0$.
The perturbative calculation gives [61,62]

$$
\lambda = \frac{\hat{\phi}_f}{4\pi^2 + 2\hat{f}_x \int_{-\infty}^{\infty} dh P(h)f''(h)^2},
\Delta(\lambda) = \frac{4\pi^2 + 2\int_{-\infty}^{\infty} dh P(h)f''(h)^3}{12\hat{f}_x^2 - \int_{-\infty}^{\infty} dh P(h)A(h)},
$$

with

$$
A(h) = f''(h)^2 - 12\hat{f}_x f''(h)f'''(h)^2 + 6\lambda^2 f''(h)^4,
$$

which should be evaluated at the transition point. We system-
atically compute the value of the breaking point $\lambda$ and
slope $\Delta(\lambda)$ at the point where $\lambda_R = 0$ in order to character-
ize the type of symmetry-breaking transition. If $\lambda \in (0, 1]$ and
$\Delta(\lambda) < 0$ it is a Gardner transition. If instead $\lambda \in [0, 1]$ but
$\Delta(\lambda) > 0$, the transition is likely to be continuous towards a
nonmarginal one-step RSB (1RSB) phase [62].

In the following, we will show results for the boundary
between simple and replica symmetry-broken phases (1RSB
and FRSB), without further solving the thermodynamics of
the glass inside the replica symmetry-broken phase. Note that
here we are mostly interested in the location of the marginally
stable FRSB glass phase.

E. Spinodal transition

A glass prepared at $(T_g, \hat{\phi}_g)$ can also be followed upon
heating ($T > T_g$), or in decompression ($\hat{\phi} < \hat{\phi}_g$, equivalently
$\eta < 0$). In that case, the glass energy becomes lower than the
one of the liquid, until a spinodal transition is reached at
$(T_{sp}, \hat{\phi}_{sp})$. In practice, the spinodal transition is found when
the solution for $\Delta$ and $\Delta_r$ disappears through a bifurcation.

This spinodal transition physically corresponds to the melting
of the glass into the liquid. At the spinodal transition ther-
monic quantities display a square-root singularity, for instance,$\hat{\epsilon}_\phi \sim \sqrt{T_{sp} - T}$.

Note that the replica symmetric solution also displays an unphysical spinodal transition in the region where it is
unstable against FRSB [40,57]. This spinodal is unphysical
because, for example, one finds that a glass might become un-
stable and melt upon cooling, which is physically inconsistent.
The correct computation of the stability limit in the region
where the replica symmetric solution is unstable should be
done by solving the FRSB equations, which goes beyond the
scope of this work. In the phase diagrams we will show in the
following, we will not draw the replica symmetric spinodal in
the region where the replica solution is unstable.

F. Jamming transition

The harmonic and WCA potentials (1) and (2) define a
physical size for the particles. Dense assemblies of particles
interacting via these two potentials will therefore have a
jamming transition at $T = 0$ and some packing fraction. For
each studied glass, we find the location of its corresponding
jamming transition point at the replica-symmetrical level. To do
so, we monitor the potential energy $\hat{\epsilon}_\phi$ of the glass [Eq. (13)]
down to $T = 0$. Depending on its value at $T = 0$, we either
compress [if $\hat{\epsilon}_\phi(T = 0) = 0$] or decompress [if $\hat{\epsilon}_\phi(T = 0) > 0$] the
zero-temperature packing until we reach the packing fraction $\hat{\phi}_J$ at which the energy changes from a finite value to zero.
The jamming transition of the initial glass occurs at
$(T = 0, \hat{\phi}_J)$, or equivalently at $(T = 0, \eta_I)$.

We stress that the location of the jamming transition de-
deps on the specific choice of the state point $(T_g, \hat{\phi}_g)$ at
which the glass was prepared in the phase diagram of Fig. 2.
It is useful to define an additional line $T_J(\hat{\phi}_J)$ in the phase di-
agram to rationalize the results in Sec. IV. This line separates
glasses into two classes: If $T_g > T_J(\hat{\phi}_J)$, the state is jammed
at $T = 0$ and $\hat{\epsilon}_\phi(T = 0) > 0$, while if $T_g < T_J(\hat{\phi}_J)$, the state
is unjammed at $T = 0$ and $\hat{\epsilon}_\phi(T = 0) = 0$.
We compute this line by taking analytically the zero-temperature limit of Eqs. (10)–(13) and solving them numerically for all initial
equilibrium glasses.

The resulting line $T_J(\hat{\phi}_J)$ for harmonic glasses is repre-
sented in Fig. 2. This line is qualitatively similar for WCA
glasses. In both models, $T_J$ is a decreasing function of $\hat{\phi}$:
Starting from better annealed glasses (lower $T_g$) shifts the
jamming transition of the glass to higher packing fractions.
This feature is also observed in the phase diagram of infinite-
dimensional hard-sphere glasses. The line $T_J$ should in prin-
ciple extend to lower packing fractions and reach $T_f$. This
is not the case in Fig. 2, as glasses prepared in this region
present an extended marginal phase at finite temperature (see,
for example, Fig. 3) and the replica symmetric solution is lost
before reaching $T = 0$. Using a FRSB solution, we would find
that this line extends smoothly to lower densities until hitting the
dynamical transition line.

IV. STATE-FOLLOWING PHASE DIAGRAMS

We now present how glasses prepared in a wide range of
conditions evolve when subject to cooling or heating and
All the glasses presented in Fig. 3 have a strictly positive potential energy at zero temperature. Indeed, they have all been prepared at temperatures $T_g$ higher than $T_f(\bar{\phi}_f = 13) = 0.013$.

Upon cooling, the simple glass may destabilize when the replicon vanishes. The slope $\Delta(\lambda)$ is formally positive for $T_g > T^*_g \approx 0.524$, indicating that glasses prepared near the dynamical transition $T^*_g < T_g < T_d$ undergo a continuous 1RSB transition towards a nonthermal phase. We find instead that for glasses prepared at $T_g < T^*_g$, such as those presented in Fig. 3, the slope $\Delta(\lambda)$ is negative at the transition. The simple glass thus transforms into a marginally stable glass at a Gardner transition, reported with circles in Fig. 3. The breaking point $\lambda$ computed with Eq. (16) at the Gardner transition equals $\lambda = 0.315, 0.159, 0.068$, and $0.01$ for $T_g = 0.5, 0.4, 0.3$, and $0.2$, respectively. Note that $\lambda \to 0$ when the Gardner transition temperature $T_G \to 0$, while $\Delta(\lambda) \to -\infty$ when $T_g \to T^*_g$ from below. We observe that the glass is marginally stable over a large temperature range when prepared at higher $T_g$. The extent of the marginally stable region diminishes for better annealed glasses (decreasing $T_g$). The Gardner transition temperature $T_G$ of a given glass decreases with decreasing $T_g$, so better annealed glasses remain stable down to lower temperatures. For the most stable glass reported in Fig. 3, prepared at $T_g = 0.1$, the glass remains stable down to zero temperature and no marginally stable phase is observed when cooling. When glasses are instead heated, their energy follows the glass equation of state up to the spinodal transition temperature $T_s$ at which the glass melts into the liquid. The temperature range over which the glass remains stable increases when the glass transition temperature $T_g$ decreases, which is the experimental hallmark of increasing glass stability [67–69].

Overall, increasing the degree of annealing of the glass extends the region of stability of the simple glass phase, pushing the marginal phase to lower (possibly vanishing) temperatures and the spinodal transition to higher temperatures.

B. Temperature-density glass phase diagram

The results of thermal quenches shown in Fig. 3 give only a partial view of the state-following phase diagrams, because density is not varied. We now study how the marginally stable phase extends in both temperature and packing fraction. Specifically, we present how glass stability modifies the extent and nature of the marginally stable phase. We compute state-following phase diagrams for glasses prepared at $\bar{\phi}_g = 13$ and different annealing, $T_g = 0.55, 0.52, 0.47, 0.4$. For each glass, we compute the Gardner transition line $T_G(\eta)$ at which the glass becomes marginally stable and we report it as a blue line in Fig. 4. As in Fig. 3, less annealed glasses first transform to a 1RSB glass, which we indicate with a blue dashed line. We expect the 1RSB glass to transform to a marginally stable 1RSB glass at lower temperature. For each $T_g$, we can also compute the replica symmetric spinodal where the glass melts into the liquid, also reported in Fig. 4 as a gray dashed line. For a given $T_g$, the region delimited by the solid and dashed lines defines the simple (replica symmetric) glass region. At temperatures below the blue line, the marginal (FRSB) glass phase exists. This phase is delimited by the blue line and
by FRSB spinodal lines that continue the gray line at lower temperatures; unfortunately, these lines can only be computed by solving the FRSB equations, which goes beyond the scope of this work. We thus interrupt the spinodal gray line when it crosses the Gardner line, but the reader should keep in mind that this line should be continued at lower temperature to properly delimit the marginal glass phase. Glasses prepared exactly at the dynamical transition \( T_\phi = T_g \) are unstable towards RSB everywhere in the glassy phase. We see in Fig. 4 that the unstable phase of glasses prepared slightly below \( T_g \) (top curve corresponding to \( T_\phi = 0.55 \)) still extends over a large region of the state-following phase diagram. As the glass preparation temperature decreases, the unstable phase becomes everywhere marginally stable and its extension diminishes. This observation is consistent with the results of the preceding section, but Fig. 4 reveals a different, more subtle, phenomenon. The shape of the Gardner transition line evolves qualitatively as \( T_\phi \) decreases. While the Gardner transition line \( T_G(\eta) \) of the less stable glasses (top curves in Fig. 4) increases monotonically with \( \eta \), it becomes nonmonotonic for lower \( T_\phi \). For very well annealed glasses, such as \( T_\phi = 0.4 \), the line even forms two disconnected regions. The marginal phase then comprises a “dome” around the jamming transition occurring at \( \eta_J = \ln(\hat{\phi}_J/\hat{\phi}_g) \) and a second region located at high compression \( \eta \), as also observed in [39]. The Gardner transition line which defines the latter region is qualitatively similar to the one found for the less stable glasses, but it is shifted to much higher packing fractions.

We argue that these two distinct marginally stable phases have a different character. The Gardner phase surrounding the jamming transition is similar to the one found by compressing hard-sphere glasses. The presence of a Gardner phase is crucial for an accurate mean-field description of jamming. The marginally stable phase at high compression appears as a remanent of the marginality which exists near the dynamical transition. It is always present, and increasing the glass stability only shifts that phase to higher density. Finally, these two distinct phases would also be present for the WCA pair potential over a range of intermediate densities, because WCA particles and harmonic spheres have the same behavior in this regime. However, WCA particles behave qualitatively differently at high densities, as described below in Sec. IV D, where the inverse power law potential is analyzed.

C. Interplay between jamming and Gardner phase

We have studied the state-following phase diagrams of many initial glasses prepared in a variety of conditions \( (T_g, \hat{\phi}_g) \). We find that the phenomenon described in the preceding section is generically observed for glasses prepared in all regions of the glass phase. For well-annealed glasses, the marginally stable phase always splits into two distinct regions. We focus on four representative well-annealed glasses \( g_1 \ldots g_4 \), prepared at state points marked by black squares in Fig. 2. These glasses are stable enough that the Gardner phase is separated into two distinct regions.

We present in Figs. 5(a)–5(d) the state-following phase diagram for each initial glass \( g_1, \ldots, g_4 \). We first determine the location of the jamming transition \( (T = 0, \hat{\phi}_J) \) for each initial glass. The value \( \eta_J = \ln(\hat{\phi}_J/\hat{\phi}_g) \) is indicated in Figs. 5(a)–5(d). We then focus on the limit of stability of the simple glass phase. For all four glasses, we draw the corresponding Gardner transition lines separating the two types of glasses, which separates into a dome around jamming and a marginal phase at high compression. We have checked that the simple glass always destabilizes to a marginally stable (FRSB) glass, as the slope \( \Delta(\lambda) \) is always negative. The parameter \( \lambda \) is finite at the left end of the dome (corresponding to the hard-sphere Gardner transition [60]) and decreases along the dome to reach \( \lambda = 0 \) at its right end, corresponding to a zero-temperature soft-sphere Gardner transition. It then increases again from \( \lambda = 0 \) at zero temperature, along the higher-density Gardner transition line. The difference between the four diagrams is the relative location of all these elements.

The glasses \( g_1 \) and \( g_2 \) are prepared below the line \( T_J \). Their jamming transition is therefore found by compressing the glass (\( \eta_J > 0 \) at \( T = 0 \)). In addition, \( |\eta_J^g| < |\eta_J^3| \) because \( g_2 \) is prepared closer to the line \( T_J \) in Fig. 2. Glasses \( g_3 \) and \( g_4 \) are prepared above \( T_J \) and their jamming transition takes place when decompressing them (\( \eta_J < 0 \) at \( T = 0 \)). Moreover, \( |\eta_J^g| > |\eta_J^4| \) because \( g_3 \) is prepared closer to \( T_J \) in Fig. 2.

For the glass \( g_1 \), the dome surrounding jamming only appears for \( \eta > 0 \) and this glass does not undergo a Gardner transition as it is cooled down to zero temperature at constant density. By contrast, the denser glass \( g_2 \) is located above the dome of marginality and that glass can undergo a Gardner transition simply by cooling. A similar qualitative difference is observed for the glasses \( g_3 \) and \( g_4 \), both prepared above the \( T_J \). The glass \( g_3 \) will become marginal if cooled at constant packing fraction, while the glass \( g_4 \) will remain stable down to its ground state. Despite these differences, all these glasses can nevertheless become marginal by a combination of cooling and compression and decompression over a broad...
range of state points. Finally, all these glasses also become marginal when compressed to large packing fractions far above jamming.

The phase diagrams found in Fig. 5 suggest the existence of two types of behaviors. Some glasses undergo a Gardner transition as they are cooled, while some glasses do not. This distinction depends both on the initial temperature $T_g$ of the glass and on its initial density $\hat{\phi}_g$. To distinguish between these two types of glasses, we define a line $T_X(\hat{\phi}_g)$ which delimits in the $(T_g, \hat{\phi}_g)$ phase diagram. Our results for $T_X$ are reported in Fig. 6. Glasses prepared in the shaded part of this phase diagram, like $g_2$ and $g_3$, undergo a Gardner transition to a marginally stable phase upon cooling at constant density. The other glasses, like $g_1$ and $g_4$, do not and remain stable glasses down to $T = 0$. The corresponding phase diagram presented in Fig. 6 is rather complex, exhibiting nonmonotonic reentrant lines $T_X$. The mean-field phase diagram of soft repulsive spheres is therefore not a trivial extension of the one of hard spheres. Figure 6 shows that a Gardner phase is relevant for hard-sphere glasses, for soft particles prepared not too far from either the dynamical transition $T_d$ and the temperature $T_J$, which suggests two distinct possible physical origins for the Gardner phase.

D. Dense liquid regime

We now focus on the dense liquid regime modeled by the IPL potential. This also corresponds to the high-density limit of the WCA model, where only the repulsive part of the Lennard-Jones interaction is physically relevant. We follow the strategy and representation adopted in Sec. IV B for the harmonic spheres.

The thermodynamic state of IPL glasses only depends on the combination $\Gamma = \hat{\phi}/T^{1/4}$. The complete phase diagram for the IPL model can therefore be completely understood.

![Figure 5](image1)

**FIG. 5.** Mean-field state-following phase diagrams for four different starting harmonic glasses (a) $g_1$, (b) $g_2$, (c) $g_3$, and (d) $g_4$, whose location in the equilibrium phase diagram is shown Fig. 1. The region of stability of the simple glass phase is delimited by the spinodal (dashed gray line) and Gardner transition line (solid blue line). Above the spinodal, the glass melts into the liquid. Below the Gardner transition line, the glass is marginally stable (shaded blue region). The jamming transition of the glasses takes place at $T = 0$ and $\eta_J$ indicated by an arrow.

![Figure 6](image2)

**FIG. 6.** Equilibrium mean-field phase diagram of harmonic spheres, as in Fig. 2. We add the transition lines $T_X$ (thin lines) which delimit the glasses that become unstable upon cooling (shaded region), such as $g_2$ and $g_3$, or not, as for $g_1$ and $g_4$. 012107-8
by fixing, for instance, the packing fraction and changing the temperature of the glass. For convenience, we choose \( \phi_g = 4.304 \), for which the dynamical transition takes place at \( T_d = 1 \). We consider glasses with different stabilities, prepared at \( T_g < T_d \). Despite the one-dimensional nature of the phase diagram, we show results for IPL glasses using the same representation as for harmonic spheres, using both \( T \) and \( \eta \), to allow for a more direct comparison of the two types of models. By definition, all lines in this diagram exactly obey the relation \( T \propto e^{\eta} \).

We find that glasses prepared at \( T_g < T_g^{\dagger} \approx 0.92 \) transform into a marginally stable glass when cooled. Instead, glasses prepared in the range \( T_g^{\dagger} < T_g < T_d \) first transform into a 1RSB glass. As for harmonic spheres, the slope \( \Delta(\lambda) \) is negative for \( T_g < T_g^{\dagger} \), diverges upon approaching \( T_g^{\dagger} \) from below, and is formally positive above it. The Gardner transition lines for glasses prepared at \( T_g = 0.9, 0.8, 0.7, \) and 0.6 are presented in Fig. 7. They have the form \( T_G(\eta) = T_G(\eta = 0) e^{\eta} \), where \( T_G(\eta = 0) \) is the Gardner transition temperature obtained for a simple cooling of the glass. The breaking point \( \lambda \) at the Gardner transition is equal to \( \lambda = 0.407, 0.283, 0.168, \) and 0.042 for \( T_g = 0.9, 0.8, 0.7, \) and 0.6, respectively. As for harmonic spheres, \( \lambda \to 0 \) when \( T_G \) vanishes. The marginally stable phase is pushed to higher densities and lower temperatures (in fact, to larger \( T \)) as the glass stability increases. In this model, however, particles do not possess a physical size (the potential has no cutoff at a finite distance) and hence the jamming transition cannot be observed. As a consequence, the domes of marginal stability found around the jamming transition in Figs. 4 and 5 for harmonic spheres are absent for the IPL model. The behavior of the Gardner transition lines at high \( \eta \) with decreasing \( T_g \) is similar in the IPL and WCA models. The WCA potential instead behaves as harmonic spheres near jamming and is thus characterized by domes around jamming.

In this dense liquid regime, glasses prepared at \( T_g < 0.567 \) remain stable down to their ground state at \( T = 0 \), as reported before [40]. The most stable glass for which we report the Gardner transition line in Fig. 7 is \( T_g = 0.6 \). Below this value, glasses remain stable in the entire phase diagram and never undergo a transition to a marginally stable phase, even at arbitrarily high compressions. This is consistent with the high-density high-temperature limit found in the harmonic phase diagram Fig. 6, where only glasses prepared in the vicinity of the dynamical transition become marginally stable upon cooling (shaded region). However, harmonic spheres are qualitatively distinct from both the WCA model and IPL potential regarding compression of very stable glasses: Whereas harmonic spheres always reach marginal states upon compression at constant temperature, very stable WCA and IPL glasses do not. Note also that for harmonic spheres, the Gardner and spinodal lines meet at high density, so the glass always melts upon high enough compression, which is not the case of the WCA and IPL models.

V. DISCUSSION AND PERSPECTIVES

In this work we have obtained the complete mean-field phase diagrams of several glass-forming models. In particular, we provided detailed information regarding the location of the marginally stable glass phases for a variety of pair interactions and physical conditions, extensively exploring physical regimes relevant to granular materials, foams, emulsions, hard and soft colloids, and molecular glasses. We find that all types of glasses may become marginally stable upon cooling or compression, but the extent of marginal phases strongly depends on the preparation protocol and the chosen model. We find that increasing the glass stability systematically reduces the extent of marginality. For well-annealed glasses, we find that marginality emerges in two distinct regions, either around the jamming transition or at high compression. Our results suggest that marginal phases should be easily observable for colloidal and non-Brownian particles near jamming or for poorly annealed glasses.

Our study unifies previous results on marginal stability in mean-field models [25,26,39,40]. Already in mean-field theory, marginal stability emerges under distinct physical conditions in different microscopic models. This provides a way to reconcile apparently contradictory numerical and experimental studies aimed at detecting Gardner phases in finite-dimensional glasses, where its existence is still debated [70,71]. In particular, the evidence for marginally stable phases reported for two- and three-dimensional hard-sphere glasses under compression contrasts with its absence in two- and three-dimensional numerical models of dense liquids upon cooling. Our analysis shows that already at the mean-field level these two types of systems behave differently. In addition, while the critical properties around the jamming transition remain unchanged from \( d = \infty \) down to \( d = 2 \) [72,73], the nature of the mean-field dynamical transition is highly altered by finite-dimensional fluctuations [74]. For instance, our results predict that highly compressed dense liquids should be marginally stable (see also [41]), a protocol that was never tested in finite-dimensional studies.
Our results will be useful to guide future numerical simulations and experiments aimed at detecting marginally stable phases in finite-dimensional glasses. We find that mean-field Gardner phases are not restricted to exist in the immediate vicinity of jamming and could be more broadly relevant to a wide class of materials. We are currently numerically investigating, along the lines of this theoretical work, the evolution of the Gardner transition while continuously interpolating between regimes relevant to dense hard-sphere glasses and dense liquids, using a WCA potential.

Our results open a number of additional perspectives for future work. One finding is that soft-sphere glasses can undergo a zero-temperature Gardner transition, as reported in Fig. 5. A convenient protocol to observe this transition is suggested in Fig. 5(d) for the glass $g_4$. It can be quenched at $T = 0$, where it is jammed and in the simple glass phase. It is therefore a stable harmonic energy minimum. Under decompression at $T = 0$, this state undergoes a Gardner transition before unjamming. The signature of this zero-temperature Gardner transition, if it exists in two or three dimensions, would be particularly dramatic: The Hessian would develop delocalized soft modes and the system would start responding by intermittent avalanches to an applied strain. A divergent correlation length would also develop in the contact network. The absence of thermal fluctuations should make the study of this transition much easier than in the thermal case.

While the nature of the mean-field Gardner transition is certainly affected in finite dimensions, the existence of extended marginally stable phases should give rise to interesting new physics in structural glasses. As happens in spin glasses, even if the Gardner phase transition is avoided in physical dimensions, it may still be the case that interesting physical phenomena, such as aging and nonlinear dynamics, remain relevant to describe the behavior of structural glasses.
